Infrared Thermographic Analysis of Craniofacial Muscles in Military Pilots Affected by Bruxism

Alberto Baldini; Alessandro Nota; Clementina Gioffi; Fabiana Ballanti; Paola Cozza

INTRODUCTION: Due to the physical stresses to which they are subjected, military pilots experience bruxism, an "oral parafuncion." Parafuncion can cause masticatory muscles suffering and serious dental, periodontal, and temporomandibular joint damage. The aim of this pilot study was to analyze the temperature distribution in masticatory and upper trapezius muscles in a sample of bruxist air force pilots, evaluating if an occlusal splint is able to induce skin temperature variations in the stomatognathic apparatus using the technology of infrared thermography.

METHODS: A total of 11 male Italian Air Force pilots of high performance aircraft, ages from 27 to 40 yr (mean 34.91 ± 2.15 yr) with 1000–3000 flight hours, were enrolled in the study and analyzed using an infrared camera in order to evaluate the temperature of the masticatory muscles. All the recordings were taken on each subject using the same protocol with and without a temporary occlusal splint.

RESULTS: The occlusal splint statistically increased each muscle temperature (0.10–0.20°C) on both the sides of the body. No statistically significant differences were found between the left and right muscles (asymmetries) before or after the wearing of the splint except for the anterior temporalis muscle. No significant improvement or variations in temperature symmetry of this muscle was found after the application of the splint.

DISCUSSION: The use of an occlusal splint could help in increasing muscles temperatures in Air Force pilots with consequent relaxation of their facial musculature system.

KEYWORDS: dental occlusion, temporomandibular disorders, occlusal splint, military personnel, muscular tension.

Air force aerobatic flight exposes pilots to accelerative stress.³⁶ Air force pilots' experiences are similar to those of high-performance athletes: both are stressed by accelerations.¹ Acceleration is the vectorial physical quantity that describes the variation of velocity in a unit of time: a = dv/dt. Modern military airplanes are capable of initiating and sustaining instantaneous acceleration forces up to +9 Gz (gravitational forces). The physiological and operational impact of acute exposures to high-G acceleration has been well documented.³⁰

Pathologies concerning dental and stomatognathic problems affecting pilots have been reported in literature. Barodontalgia, the dental pathology that is diagnosed with the highest frequency, occurs in 11% of air force aircrews at a rate of 5 episodes/1000 flights.²³ Another pathology, frequently reported during the WWII period, deals with fracturing of restorations during high-altitude flying and is called "dental barotrauma."²⁴

It is generally accepted that chronic stressful situations and mental diseases contribute to the development of occlusal parafuncions and temporomandibular disorders without being the only cause.²³ Air force pilots, due to the physical stresses to which they are subjected, can experience bruxism, an oral parafuncion that can cause masticatory muscle pain, serious dental and periodontal damage, and temporomandibular joint disorders (TMD).⁶ TMD is a multifactorial pathology, difficult to diagnose and characterized by an alteration of the masticatory muscles.

limitation of jaw movement, pain, joint noises, and other symp-
toms. In 2007, Lurie et al. performed a study in which a sig-
nificant percentage (69%) of Israeli air force pilots analyzed
were affected by bruxism; the authors suggested the utility of a
protective treatment for the teeth.

In air force pilots, it is important to evaluate various aspects of
the masticatory muscles, such as temperature, due to the high
stress which this component of the stomatognathic system is
subjected to. Stomatognathic diseases, such as myogenous TMD and
bruxism, can alter the temperature of masticatory muscles be-
because it is dependent not only on energy production, but also
blood flow. TMD and bruxism are characterized by hyperactivity
of the masticatory muscles, which changes the microcirculatory
dynamics due to compression of blood vessels, resulting in a
decrease of skin temperature. Thus, in the masticatory system,
lower temperatures are typical of muscular hyperactivity while
higher temperatures are related to muscular relaxation.

To measure peripheral temperature, infrared thermography
is applied and is able to detect variations of skin tempera-
ture, showing changes in the muscular activity of the masticatory
system. Thermography analyzes body infrared radiation
with a temperature above absolute zero and is used as an effective
tool for the diagnosis of various diseases given its efficiency
in analyzing the distribution of skin surface temperature. Control of heat transfer with the environment plays a fundamental role for body temperature regulation; indeed, the skin temperature distribution of the human body depends on the complex relationships defining the heat exchange processes between skin tissue, inner tissue, local vasculature, and metabolic activity. Some great advantages of infrared thermography are that it is not an invasive exam, but a "touchless" and dynamic imaging investigation technique. Some studies have been carried out with infrared thermography to measure the skin surface temperature of the masticatory muscles and tem-
poromandibular joint in individuals with TMD.

It is well established in the field of thermography that healthy,
symptom-free patients show thermal symmetry between the
right and the left sides of the body. Studies have shown that in
healthy persons, temperatures of the body (including the face)
were essentially bilaterally equal, with an average temperature
difference from side to side, termed AT, of only 0.2°C. The
literature is still conflicted about the trustworthiness of this
instrument in the diagnosis of TMD because of the difficulty
matching its results with the results of the Research Diagnostic
Criteria for Temporomandibular Disorders system. The aim
of this pilot study was to analyze the temperature distribution
in the masticatory and upper trapezius muscles in a sample of air
force pilots, evaluating if an occlusal splint was able to induce
skin temperature variations in the stomatognathic apparatus.

**METHODS**

**Subjects**

A total of 11 male Italian Air Force pilots of high performance
aircraft, ages from 27 to 40 yr (mean 34.91 ± 2.15 yr) with
1000–3000 flight hours, were enrolled in the study and ana-
alyzed at the Institutes of Aerospace Medicine in Milan. These
pilots were all members of the P.A.N. (National Acrobatic Patrol)
and they signed a consent form after being fully informed
about the nature of the study. A clinical examination and anam-

**Equipment**

An infrared camera FLIR Systems® (Arlington, VA) Therma-
CAM SC640 with resolution of 640 × 480 pixels was used in
order to evaluate the temperature of the right and left masseter,
right and left anterior temporals, right and left upper trapezius,
and right and left sternocleidomastoid muscles. The instrument
was stabilized for 10 min before the exam.

**Procedure**

The study protocol was approved by the relevant ethical com-
mittee of the Italian Air Force's Forensic Medicine Medical
Commission. The participants were asked to avoid hot showers
or baths, topical agents, creams or powders, or nasal deconges-
tants, vigorous exercise, or intake of stimulants such as caffeine
2 h before data collection. During the examination, the pilots
stayed in an acclimatized room for 20 min with a temperature
of 22 ± 0.1°C, an aeration of 0.3 ± 0.2 m · s⁻¹, and a relative
humidity of 48 ± 1%. The subjects were positioned in the
upright position without shoes on a posture scale analyzer
with the head positioned with the Frankfurt plane parallel to
the ground at a distance from the front lens of the camera of 2 ± 0.1
m. The region of the muscles analyzed was cleared of clothes
and personal items.

In order to evaluate the temperature we used the line tool of
the software. This instrument delimits the entire length of the
muscles we wanted to study and generates a thermic plan
(Fig. 2). For the masseter muscle, the starting point of the line
tool was positioned in the zygomatic arch and the final part in
the lateral surface of the angle of mandible; for the anterior
temporalis muscle, the initial point of the line tool was placed
on the frontal bone, immediately above the muscle belly, and
the final portion near the eyelid lateral commissure; for the
upper trapezius muscle, the starting part of the line tool was
positioned on the C7 spinous process and the final part on the

![Fig. 1. Clinical intraoral image showing signs of bruxism in an air force pilot involved in the study.](image)
acromion; for the sternocleidomastoid the initial part of the line tool was positioned on the mastoid process and the final part near the collarbone. The average temperature of the entire line extension was generated along the entire length of the delimited muscle. In order to exclude potential interrater variability, the same operator performed all analyses.

A temporary occlusal splint was fabricated for each subject using Easybite® (Techim Group S.r.l., Milano, Italy). Easybite® consists of a PVC tube, shaped to adapt to the dental arch, that can be filled with a photopolymerizable fluid (Fig. 3 and Fig. 4). An expert operator inserts the Easybite® into the subject’s mouth and adds the fluid in order to obtain the ideal shape while asking the patient to bite lightly the tube. In this study the Easybite® was used in a centric relation with Dawson’s bilateral manipulation, which is a manual technique that allows the gnatologist to position the mandible and its condyles in a recordable and modifiable position. Studies in literature concluded this technique to be trustworthy and reliable for recording the patient’s centric relation position.3

The operator stands behind the patient and places three fingers (first finger, middle finger, and ring finger) under the horizontal branch of the mandible with the thumb firmly positioned on the chin and the little finger on the rear of the vertical branch of the mandible so the operator can pull the mandible, allowing the condyles to return to the glenoid cavity.6 Once the operator has obtained the bite in centric relation, the fluid can be photopolymerized.

All the recordings were taken on each subject using the same protocol with and without the Easybite® with a pause of 2 h between the recordings. The pilot was asked to have the Easybite® between his dental arches during 30 min of staying in the acclimatized room before the recording. A Student’s t-test was applied for analyzing the differences between the recordings (statistical significance was set at $P < 0.05$).

RESULTS

Table I displayed the mean temperature of the muscles on the right and left sides as affected by the occlusal splint. Analyzing the results obtained, it was observed that wearing the occlusal splint statistically increased each muscle temperature on both sides ($P < 0.01$) (Table I). No statistically significant differences were found between the left and right muscles (asymmetries) before or after the wearing the splint except for the anterior temporalis muscle ($P = 0.019$ before and $P = 0.023$ after). No significant improvement or variations in temperature symmetry of this muscle was found after the application of the splint.

DISCUSSION

Some authors have stated that thermography is a record of the heat produced by facial vessels and by the cellular metabolism during muscular activity. Thermography was used in some studies in the dental field in order to analyze its usefulness in the analysis of TMD and stomatognathic diseases with contrasting results about the accuracy in diagnosis. Stomatognathic system diseases such as TMD, inflammations, or muscle and ligament injuries can alter the temperature of the compromised structures and these variations can be detected by telethermographic analysis. Also, bruxism can alter the craniofacial muscles’ temperature owing to their consequent hyperactivity.

A study made by Lurie et al. demonstrated that 69% of air force pilots were affected by bruxism and dental occlusion. Thus, an occlusal splint treatment, in which the subject performs an isometric contraction of the mandibular elevator muscles, could be useful for relaxing their masticatory muscles, balancing the occlusal contacts and forces by changes in the rest position due to tooth clenching, which may or may not be related to emotional stress. Moreover, if carefully built, the splint could enhance their postural control, preventing painful lumbar and cervical symptomatology.

In this study a temporary occlusal bite was built using Easybite® for analyzing the thermographic effect on air force pilots' facial muscles consequent to the wearing of this splint. Barao et al. showed that the use of an acrylic splint in a sample of diagnosed myofascial TMD statistically increased the muscles' temperature after approximately 3 mo therapy. These findings corroborate with the results of the present study, since the temperature changed after the Easybite® was worn for 20 min.

Notwithstanding, these pilots were not affected by TMD. Their facial muscle tension probably correlated to their bruxism; wearing the temporary splint succeeded in relaxing their muscular system, increasing their facial muscle temperature.

In this study the thermal patterns of the stomatognathic system present a high level of symmetry between the two sides, according to other authors, except for the anterior temporalis that, according to McBeth and Gratt showed statistical significance between the left and right sides. This may be related to the presence of a parafunction (bruxism), but not the absence of TMD in this sample of air force pilots.

After wearing the occlusal splint, no significant improvement of the temperature asymmetry of the anterior temporalis muscle were recorded, contrary to Barao et al. Barao et al. found that the mean temperature of the masseter muscle prior to treatment was around 34.2°C, while in patients with arthritis was significantly lower (33.5°C). Similar to that, in this study, the simple application of the occlusal splint caused an increase from 33.39°C to 33.75°C in the masseter muscle.

It should be remembered that, compared to other studies, these results were obtained after only 20 min of application of the occlusal splint. Thus, the significant results of this study are important as a starting point for the planning of a detailed study about the use of an occlusal bite in air force pilots in order to protect their stomatognathic apparatus from bruxism and other stresses and relax their muscles, balancing their occlusal and muscular system.

The principal limitations of this study are the small sample size and the use of a temporary splint for only 20 min. Therefore, additional studies are required to evaluate the muscular temperature changes after prolonged occlusal bite therapy in air force pilots. Within the limitations of this study, the use of an occlusal splint could help in increasing muscle temperatures in air force pilots, with consequent relaxation of their facial muscular system. Bruxist pilots present an asymmetry between the temperatures of the anterior temporalis muscle of the left and right side that cannot be balanced after only 20 min of occlusal splint wearing.
